2. Joint Institute for the Study of the Atmosphere and Ocean, Seattle, Washington

Abstract This report addresses the development, validation and stability tests of a tsunami forecast model for Seward, Alaska. The forecast model employs the numerical code “Method of Splitting Tsunamis” for real-time simulation of tsunami propagation and runup in three telescoped computational grids. The innermost grid covers the Seward city at a resolution of 3'' (~ 44 m along longitude and ~ 93 m along meridian). The model is designed to complete a 10-hour simulation within 7 minutes of CPU time. Accuracy and stability of the model are proved in the tests employing historical tsunami events and hypothetical scenarios.

1 Background and Objectives

The National Oceanic and Atmospheric Administration (NOAA) Center for Tsunami Research (NCTR) at the NOAA Pacific Marine Environmental Laboratory (PMEL) has developed a tsunami forecasting capability for operational use by NOAA's two tsunami warning centers located in Hawaii and Alaska (Titov et al., 2005). The system, termed Short-term Inundation Forecast of Tsunamis (SIFT), is designed to efficiently provide accurate basin-wide warnings of approaching tsunami waves quickly. It combines real-time tsunami event data with numerical models to produce estimates of tsunami wave arrival times and amplitudes at coastal communities of interest. The SIFT system integrated several key components: the tsunameters for real-time monitoring of tsunami signals in deep ocean, a basin-wide pre-computed propagation database of water level and flow velocities based on potential seismic unit sources, an inversion algorithm to derive the tsunami source based on tsunameter observations during a tsunami event, and stand-by inundation forecast models to provide accurate and speedy numerical modeling of tsunami impact for coastal communities. For technical aspects of forecast model development, validation, and stability testing, readers are referred to Synolakis et al. (2008) and Tang et al. (2008).

Seward is located at the head of Resurrection Bay on the Kenai Peninsula of Alaska. It is approximately 125 miles to the south of Anchorage. The city has a population of 2693 living in an area of 14.4 square miles (2010 Census). Seward is home to a busy fishing port, as well as serving seasonal Alaska cruise ship visitors. Unlike many coastal communities in Alaska, Seward is accessible by many means including boat, seaplane, railroad, bus, and automobile. Its location and proximity to the railroad make it the terminus of many leisure cruises. The Seward harbor remains ice free in all seasons, making it a critical supply center for the interior of Alaska.

Like many Alaskan communities along the Pacific coast, Seward is under the threat of tsunamis. This city is within the Alaska-Aleutian megathrust zone, one of the most seismically active areas in the world. In history, Seward has been attacked by most major tsunamis in the Pacific. On March 27, 1964, a tsunami was generated by an Mw 9.2 earthquake in Prince William Sound (Suleimani et al., 2010). The earthquake also triggered a landslide in Seward area that generated a local tsunami (Lander, 1996). During this event, water waves of 6–8 m were observed in the north Resurrection Bay and 12 people were killed in Seward.

In this report, we develop a tsunami forecast model for Seward. This model is to be incorporated into the SIFT system for use at the tsunami warning centers.

2 Forecast Methodology

Ocean-scale simulations of tsunami propagation are very time-consuming. To expedite tsunami forecasts, a propagation database has been developed in the SIFT system (Gica et al., 2008). The database is composed of “unit tsunami sources”, or simply “unit sources”. A unit source is the pre-computed time-series of water surface elevations and water velocities in the oceanic basin due to a “unit earthquake source”. Each unit earthquake source has a fault length of 100 km, a width of 50 km, and a slip of 1.0 m, equivalent to an earthquake of Mw 7.5. Other parameters, such as dip and rake angles, are defined to be the most effective regarding tsunami generation. The initial water surface elevations due to a unit earthquake

source are estimated through Okada's (1985) model. The propagation of generated water waves is computed with a numerical code, Method of Splitting Tsunami (MOST), which solves the nonlinear shallow water equations through a finite difference algorithm. MOST has been extensively validated against laboratory experiments and benchmarks (Synolakis et al., 2008), and successfully applied to numerous historical tsunami events (e.g., Wei et al., 2008; Tang et al., 2008). All basin-scale simulations are conducted at a resolution of 4'. At current stage, the propagation database has covered all potential tsunamigenic subduction zones in the Pacific and Atlantic Oceans.

After a tsunami is generated, as the waves propagate across the ocean and successively reach the DART ("Deep-Ocean Assessment and Reporting of Tsunamis") tsunamieters, measured water level is ingested into the tsunami forecast application in near real-time and incorporated into an inversion algorithm to produce an improved estimate of the tsunami source (Percival et al., 2009). A linear combination of unit sources is then performed based on this tsunami source to produce synthetic boundary conditions to initiate the computation of forecast models.

The main objective of forecast models is to provide an accurate, yet rapid, estimate of arrival time, wave heights, and inundation in the minutes following a tsunami event. The core of a forecast model is a numerical model, which simulates the nearshore propagation and inundation of tsunamis at high resolution in real time. The forecast models are designed and tested to perform under stringent time constraints, given that time is generally the single limiting factor in saving lives and properties. The simulations are performed with MOST in three telescoped grids at successively increased resolutions. Boundary conditions of the outermost grid include water surface elevations and water velocities derived from the linear combination of unit sources. The innermost grid covers the population and economic center of the community. High resolutions in the grids are necessary for computational accuracy. On the other hand, higher resolution requires more computational resources and consumes longer CPU time. The development of a forecast model considers a balance between accuracy and computational efficiency. Previous and present development of forecast models in the Pacific area have validated the accuracy and efficiency of each forecast model currently implemented in the SIFT system (Titov et al., 2005; Titov, 2009; Tang et al., 2008; Wei et al., 2008).

3 Model Development

Tsunami forecast for a coastal community is accomplished through real-time simulations of tsunami propagation and inundation in three nested grids. The basis for the development of these grids is the high-resolution digital elevation models (DEMs). From these DEMs, three high-resolution, "reference" elevation grids are constructed for the development of a high-resolution reference model. From this reference model, an "optimized" model at lower resolution is constructed to run in an operationally specified period of time. This operationally developed model is referred to as the optimized tsunami forecast model, or simply the "forecast model".

The accuracy of a forecast model highly depends on the accuracy of bathymetry and topography. The present forecast model is based on a DEM provided by NOAA National Geophysical Data Center, and we consider it to be an adequate representation of the local to-

pography and bathymetry. As new DEMs become available, forecast models will be updated and report updates will be posted at “http://nctr.pmel.noaa.gov/forecast_reports”.

3.1 Forecast area

The city of Seward sits on a flat and low-lying delta at the head of Resurrection Bay on the Kenai Peninsular (Figure 1). Resurrection Bay is a deep fjord with a maximum water depth of approximately 300 m. The deep flat depression in the middle of the bay bottom extends north to south, roughly parallel to the fjord. This configuration is effective to propagate waves from the entrance to the head. The water body is semi-closed by a group of isles at its entrance, which helps block some energy of tsunamis propagating into the bay from outside Gulf of Alaska.

3.2 Grid configuration

The computational grids in the forecast model are presented in Figure 2. Their parameters can be found in Table 1. In the forecast model, the A-grid provides a transition from the propagation database to real-time simulations. Its offshore boundaries are extended into deep ocean, where linear assumption of hydrodynamic processes is valid. The C-grid covers the entire Seward city at a resolution of $3.0''$, which is approximately 46.2 m along longitude and 92.8 m along latitude, respectively. Moving boundaries are only allowed in C-grid. In A- and B-grids, we install an artificial wall of infinite height along the -1.0 m contour offshore. A Manning’s n of 0.03 is employed in all grids to consider the effects due to bottom friction. As shown in Figure 3, there is a tide gage at the Seward harbor (60.12°N , 149.427°W), where the water depth is 4.831 m under mean high water level and the mean range of tide is 2.539 m. The present gage was installed on Jun 26, 1989.

A reference model is also developed in parallel. In the reference model, A-grid has a larger domain coverage than that of the forecast model in order to investigate the effects of grid extents. B- and C-grids have the same extents as those in the forecast model. All other configurations are the same in both models except that the reference model has higher resolution. This is to check the effects of numerical errors that can be introduced in the numerical models.

4 Model Testing

Accuracy and stability are the two key characteristics of a forecast model. Accuracy requires that the errors in computed arrival time, wave heights, and coastal runup are below a specific level. The major parameters that govern the accuracy of a forecast model include topography and bathymetry, as well as spatial resolution. In developing the models, we construct the computational grids from the high-resolution DEMs that are derived from the best available bathymetric and topographic data sets. Resolutions in the forecast model are downgraded from the reference grids to save CPU time. Stability, which requires that the model works smoothly in all possible scenarios, is as important as accuracy for it guarantees the reliability of the forecast system. Instability most likely to happen as a result of very high input wave

heights. In some cases, very low wave heights may also cause instability if the amplitude of numerical errors is comparable to that of input waves.

4.1 Accuracy and model validation

In this section, we first investigate the accuracy of the forecast model against historical tsunami events. Epicenters of the triggering earthquakes are shown in Figure 4, and describing parameters are presented in Tables 2. The historical events are simulated with both forecast and reference models. By comparing the two models for time-series of water levels at the tide gage and distributed maximum water surface elevations in all grids, we qualitatively evaluate the effects due to different resolutions. The tide gage near the Seward coast has recorded several tsunamis affecting this area. Among them, the 2010 Chile event was generated by an earthquake of Mw 8.8 and water waves of approximately 0.5 m were observed at the tide gage. This event provides a good benchmark to validate the models. In most other events, the signals are too weak and noisy to be applied to model validation.

Figures 5–14 show an agreeable comparison between the forecast and reference models in all historical events. In general, the agreement is very good at the leading waves. Differences are usually significant in shorter trailing waves, probably because the numerical errors caused by coarser resolutions become relatively higher in these waves. On the other hand, these errors may not affect the forecast significantly as maximum coastal inundation is mostly caused by longer waves. In Figure 13, we also compare the computed water levels with those measured at the tide gage during the 2010 Chile event. Both models are very accurate at the first wave peak.

In the Pacific basin, there are several seismically active zones, where mega thrusts may happen and trigger tsunamis that bring severe floods to the Seward city. The Seward forecast and reference models are also tested for possible mega tsunami scenarios. In Figure 15, we present the locations of possible triggering earthquakes. Their parameters are described in Table 3. Each scenario involves 20 unit sources with 30 m slips, equivalent to an Mw 9.0 earthquake. Mega tsunamis originating in the nearest Alaska-Aleutian-Cascadia subduction zone (ACSZ) are extremely hazardous to the Seward area as the water waves may not lose much energy due to radiation in the open ocean. For example, we observe water waves of more than 2 m at the tide gage in scenarios of ACSZ 22-31 (Figure 16) and ACSZ 50-59 (Figure 17). These tsunamis are hazardous also because, after generated, they can arrive at the Seward city within a short time, say less than 4 hours. We also note that, in the scenario of CSSZ 102-111 (Figure 18), although the waves need to propagate over a very long distance in the open ocean, they still bring extremely severe impact in Seward area. Wave heights and coastal runup caused in this scenario are far higher than those in the scenario of KISZ 1-10 (Figure 19), even though the epicenter in later scenario is far closer. This is because the oceanic propagation of tsunamis has directivity, e.g., a great amount of wave energy is projected along a few specific directions. As shown in Figure 20, Seward is in a major passage of tsunami propagation in the scenario of CSSZ 102-111.

In Figures 21 and 22, we also compare the forecast and reference models for time-series of water levels at the tide gage in other hypothetical scenarios of mega and smaller tsunamis. It is consistent that agreement is better for longer waves but worse for shorting waves. In scenarios of micro tsunamis, the agreement becomes very poor in the trailing waves. This

may be because that the amplitudes of numerical errors become comparable to those of the water waves themselves. For the scenario of NTSZ B36, in which the maximum wave height is only approximately 5 mm at the tide gage, we still obtain a very good agreement between the two models.

For a 10-hour simulation, the forecast model consumes less than 7 minutes of CPU time on a 2×6 core @ 2.93 GHz computer in linux 64 RH4 environment, while the reference model requires nearly 120 minutes. The forecast model is adequately accurate and fast for real-time forecasts.

4.2 Stability

No stability issue is observed in the forecast model in above tests. The mega tsunami scenarios represent extremely harsh situations of very low probability. In the models, a minimum input water surface displacement of 0.0001 m is required to initiate the real-time simulations. This criterion is temporarily lowered to 1.0×10^{-6} m in the micro tsunami scenarios or the simulations cannot be started. The performance of the forecast model in these tests suggests that it is very stable and will be unlikely to fail in real-time forecasts if integrated into the SIFT system.

5 Summary and Conclusions

In this report, we document the development and test of a tsunami forecast model for Seward, Alaska. This model is to be implemented into the SIFT system that provides real-time forecast of tsunamis for U.S. coastal communities with tsunami hazards. The model grids are constructed based on a high-resolution DEM derived from the best available bathymetric and topographic data sets. The population and economic center of Seward city is covered by a grid at a resolution of 3'', which is equal to approximately 46 m along longitude and 93 m along the meridian. The model is designed to complete a 10-hour simulation within 7 minutes of CPU time.

A reference model at higher-resolutions is also developed in parallel. Accuracy of the forecast model is investigated mainly through the comparison of numerical results between the two models. The model testing employs a series of historical events and hypothetical scenarios of mega and micro tsunamis. Agreement between the two models, as well as with historical measurements, indicates the forecast model is sufficiently accurate regarding real-time forecast. Very good robustness of the forecast model is also observed in the tests.

Figure 6: Model results for the 1957 Andreanov event: maximum water surface elevations (m) in reference model A- (a), B- (b), and C-grids (c), in forecast model A- (d), B- (e), and C-grids (f), and time-series of water surface elevations at the tide gage (indicated as black triangles in C-grids).

Figure 7: Model results for the 1994 Kuril Islands event: maximum water surface elevations (m) in reference model A- (a), B- (b), and C-grids (c), in forecast model A- (d), B- (e), and C-grids (f), and time-series of water surface elevations at the tide gage (indicated as black triangles in C-grids).

Figure 8: Model results for the 1996 Andreanov event: maximum water surface elevations (m) in reference model A- (a), B- (b), and C-grids (c), in forecast model A- (d), B- (e), and C-grids (f), and time-series of water surface elevations at the tide gage (indicated as black triangles in C-grids).

Figure 9: Model results for the 2006 Kuril Islands event: maximum water surface elevations (m) in reference model A- (a), B- (b), and C-grids (c), in forecast model A- (d), B- (e), and C-grids (f), and time-series of water surface elevations at the tide gage (indicated as black triangles in C-grids).

Figure 10: Model results for the 2007 Peru event: maximum water surface elevations (m) in reference model A- (a), B- (b), and C-grids (c), in forecast model A- (d), B- (e), and C-grids (f), and time-series of water surface elevations at the tide gage (indicated as black triangles in C-grids).

Figure 11: Model results for the 2007 Chile event: maximum water surface elevations (m) in reference model A- (a), B- (b), and C-grids (c), in forecast model A- (d), B- (e), and C-grids (f), and time-series of water surface elevations at the tide gage (indicated as black triangles in C-grids).

Figure 12: Model results for the 2009 Samoa event: maximum water surface elevations (m) in reference model A- (a), B- (b), and C-grids (c), in forecast model A- (d), B- (e), and C-grids (f), and time-series of water surface elevations at the tide gage (indicated as black triangles in C-grids).

Figure 13: Model results for the 2010 Chile event: maximum water surface elevations (m) in reference model A- (a), B- (b), and C-grids (c), in forecast model A- (d), B- (e), and C-grids (f), and time-series of water surface elevations at the tide gage (indicated as black triangles in C-grids). Computed time-series are shifted +8 minutes for better agreement in (g).

Figure 14: Model results for the 2011 Tohoku event: maximum water surface elevations (m) in reference model A- (a), B- (b), and C-grids (c), in forecast model A- (d), B- (e), and C-grids (f), and time-series of water surface elevations at the tide gage (indicated as black triangles in C-grids).

Figure 15: Epicenters of triggering earthquakes in synthetic mega tsunami scenarios employed to test the Seward, AK forecast and reference models. Location of Seward is indicated as a triangle.

Figure 16: Model results for synthetic scenario of ACSZ 22–31: maximum water surface elevations (m) in reference model A- (a), B- (b), and C-grids (c), in forecast model A- (d), B- (e), and C-grids (f), and time-series of water surface elevations at the tide gage (indicated as black triangles in C-grids).

Figure 17: Model results for synthetic scenario of ACSZ 50–59: maximum water surface elevations (m) in reference model A- (a), B- (b), and C-grids (c), in forecast model A- (d), B- (e), and C-grids (f), and time-series of water surface elevations at the tide gage (indicated as black triangles in C-grids).

Figure 18: Model results for synthetic scenario of CSSZ 102–111: maximum water surface elevations (m) in reference model A- (a), B- (b), and C-grids (c), in forecast model A- (d), B- (e), and C-grids (f), and time-series of water surface elevations at the tide gage (indicated as black triangles in C-grids).

Figure 19: Model results for synthetic scenario of KISZ 1–10: maximum water surface elevations (m) in reference model A- (a), B- (b), and C-grids (c), in forecast model A- (d), B- (e), and C-grids (f), and time-series of water surface elevations at the tide gage (indicated as black triangles in C-grids).

Figure 20: Maximum water surface elevations (m) in the Pacific basin. The red star indicates the location of Seward, Alaska.

Figure 21: Time-series of water surface elevations at the tide gage in mega tsunami scenarios computed with reference model (red) and forecast model (blue), respectively.

Figure 22: Time-series of water surface elevations at the tide gage in micro-tsunami and Mw 7.5 scenarios computed with reference model (red) and forecast model (blue), respectively.

Table 1: MOST setup of the reference and forecast models for Seward, Alaska.

Grid	Region	Reference Model				Forecast Model			
		Coverage	Resolution	nx×ny	Time	Coverage	Resolution	nx×ny	Time
		Lat. (°N)	Lat.		Step	Lat. (°N)	Lat.		Step
Lat.	Lon. (°W)	Lon.		(sec.)		Lon. (°W)	Lon.		(sec.)
A	Gulf of Alaska	55.0–61.8 156.0–146	48'' 48''	751×511	2.4	56.0–60.5 154.97–147.97	120'' 120''	211×136	8.5

A Model *.in files for Seward, Alaska

A.1 Reference model *.in file

```
0.0001    Minimum amp. of input offshore wave (m)
1.0        Minimum depth of offshore (m)
0.1        Dry land depth of inundation (m)
0.0009    Friction coefficient (n**2)
1          run up in a and b
300.0     max wave height meters
0.3        time step (sec)
120000   number of steps for 10 h simulation
8          Compute "A" arrays every n-th time step, n=
3          Compute "B" arrays every n-th time step, n=
96         Input number of steps between snapshots
1          ...starting from
1          ...saving grid every n-th node, n=
```

A.2 Forecast model *.in file

```
0.0001    Minimum amp. of input offshore wave (m)
1.0        Minimum depth of offshore (m)
0.1        Dry land depth of inundation (m)
0.0009    Friction coefficient (n**2)
1          run up in a and b
300.0     max wave height meters
0.85       time step (sec)
42353    number of steps for 10 h simulation
10         Compute "A" arrays every n-th time step, n=
3          Compute "B" arrays every n-th time step, n=
30         Input number of steps between snapshots
1          ...starting from
1          ...saving grid every n-th node, n=
```

C Forecast Model Testing

Author: Lindsey Wright

C.1 Purpose

Forecast models are tested with synthetic tsunami events covering a range of tsunami source locations and magnitudes. Testing is also done with selected historical tsunami events when available.

The testing of a forecast model has three objectives. The first objective is to assure that the results obtained with the NOAA's tsunami forecast system software, which has been released to the Tsunami Warning Centers for operational use, are consistent with those obtained by the researcher during the development of the forecast model. The second objective is to test the forecast model for consistency, accuracy, time efficiency, and quality of results over a range of possible tsunami locations and magnitudes. The third objective is to identify bugs and issues in need of resolution by the researcher who developed the Forecast Model or by the forecast system software development team before the next version release to NOAA's two Tsunami Warning Centers.

Local hardware and software applications, and tools familiar to the researcher(s), are used to run the Method of Splitting Tsunamis (MOST) model during forecast model development. The test results presented in this report lend confidence that the model performs as developed and produces the same results when initiated within the forecast system application in an operational setting as those produced by the researcher during the forecast model development. The test results assure those who rely on the Seward tsunami forecast model that consistent results are produced irrespective of system.

C.2 Testing Procedure

The general procedure for forecast model testing is to run a set of synthetic tsunami scenarios and a selected set of historical tsunami events through the forecast system application and compare the results with those obtained by the researcher during the forecast model development and presented in the Tsunami Forecast Model Report. Specific steps taken to test the model include:

1. Identification of testing scenarios, including the standard set of synthetic events, appropriate historical events, and customized synthetic scenarios that may have been used by the researcher(s) in developing the forecast model.
2. Creation of new events to represent customized synthetic scenarios used by the researcher(s) in developing the forecast model, if any.
3. Submission of test model runs with the forecast system, and export of the results from A, B, and C grids, along with time series.
4. Recording applicable metadata, including the specific forecast system version used for testing.

5. Examination of forecast model results for instabilities in both time series and plot results.
6. Comparison of forecast model results obtained through the forecast system with those obtained during the forecast model development.
7. Summarization of results with specific mention of quality, consistency, and time efficiency.
8. Reporting of issues identified to modeler and forecast system software development team.
9. Retesting the forecast models in the forecast system when reported issues have been addressed or explained.

Synthetic model runs were tested on a DELL PowerEdge R510 computer equipped with two Xeon E5670 processors at 2.93 Ghz, each with 12 MBytes of cache and 32GB memory. The processors are hex core and support hyperthreading, resulting in the computer performing as a 24 processor core machine. Additionally, the testing computer supports 10 Gigabit Ethernet for fast network connections. This computer configuration is similar or the same as the configurations of the computers installed at the Tsunami Warning Centers so the compute times should only vary slightly.

C.3 Results

The Seward forecast model was tested with SIFT version 3.2.

The Seward, Alaska forecast model was tested with four synthetic scenarios and one historical event. Test results from the forecast system and comparisons with the results obtained during the forecast model development are shown numerically in Table C1 and graphically in Figures C1 to C5. The results show that the minimum and maximum amplitudes and time series obtained from the forecast system agree with those obtained during the forecast model development, and that the forecast model is stable and robust, with consistent and high quality results across geographically distributed tsunami sources. The model run time (wall clock time) was 4.78 minutes for 9.99 hours of simulation time, and 1.88 minutes for 4.0 hours. This run time is well within the 10 minute run time for 4 hours of simulation time and satisfies run time requirements.

A suite of four synthetic events was run on the Seward forecast model. The modeled scenarios were stable for all cases run. Wave heights were greater than 50 centimeters (cm) for all source zones tested. The largest modeled height was 247 cm from the Central and South America (ACSZ 56-65) source zone. The smallest signal of 62 cm was recorded at the Kamchatka-Yap-Mariana-Izu-Bonin (KISZ 22-31) source zone. Maximum and minimum values from development were not available but visual comparisons between the development cases and the forecast system output were consistent in shape and amplitude for both the Tohoku 2011 historical event and tested synthetic events. The Seward reference point used for the forecast model development is the same as what is deployed in the forecast system, so the results can be considered valid for the cases studied.

Figure C1: Response of the Seward forecast model to synthetic scenario KISZ 22-31 ($\alpha=30$). Maximum sea surface elevation for (a) A-grid, (b) B-grid, (c) C-grid. Sea surface elevation time series at the C-grid warning point (d).

Figure C2: Response of the Seward forecast model to synthetic scenario ACSZ 56-65 ($\alpha=30$). Maximum sea surface elevation for (a) A-grid, (b) B-grid, (c) C-grid. Sea surface elevation time series at the C-grid warning point (d).

Figure C3: Response of the Seward forecast model to synthetic scenario CSSZ 102-111 ($\alpha=30$). Maximum sea surface elevation for (a) A-grid, (b) B-grid, (c) C-grid. Sea surface elevation time series at the C-grid warning point (d). The lower time series plot (d) is the result obtained during model development and is shown for comparison with test results.

Figure C4: Response of the Seward forecast model to synthetic scenario NTSZ 30-39 ($\alpha=30$). Maximum sea surface elevation for (a) A-grid, (b) B-grid, (c) C-grid. Sea surface elevation time series at the C-grid warning point (d).

Figure C5: Response of the Seward forecast model to the 2006 Tonga tsunami. Maximum sea surface elevation for (a) A-grid, (b) B-grid, (c) C-grid. Sea surface elevation time series at the C-grid warning point (d). The lower time series plot (e) is the result obtained during model development and is shown for comparison with test results.

Table C1: Run time of the Seward, Alaska forecast model.

Model	Modeled Time [hrs]	Wall Time [min]	4-hour Time [min]	Space [Gb]	12-hour Space [Gb]
